Exercise-associated hyponatremia (EAH) typically occurs during or up to 24 hours after prolonged physical activity, and is defined by a serum or plasma sodium concentration below the normal reference range of 135 mEq/L. It is also reported to occur in individual physical activities or during organized endurance events conducted in austere environments in which medical care is limited or often not available, and patient evacuation to definitive care is often greatly delayed. Rapid recognition and appropriate treatment are essential in the severe form to ensure a positive outcome. Failure in this regard is a recognized cause of event-related fatality. In an effort to produce best practice guidelines for EAH in the austere environment, the Wilderness Medical Society convened an expert panel. The panel was charged with the development of evidence-based guidelines for management of EAH. Recommendations are made regarding the situations when sodium concentration can be assessed in the field and when these values are not known. These recommendations are graded based on the quality of supporting evidence and balance between the benefits and risks/burdens for each parameter according to the methodology stipulated by the American College of Chest Physicians.

**Key words**: hyponatremia, exercise-associated hyponatremia, arginine vasopressin, SIADH, exercise

**Introduction**

Nearly 3 decades after the first report of exercise-associated hyponatremia (EAH),1 great strides are taking place in an effort to prevent what is now recognized as a leading cause of preventable morbidity and mortality in endurance activities throughout the world. To date, review articles and international consensus statements have documented risk factors, pathophysiology, signs and symptoms, prevention, and patient management strategies.2–8 These reports have primarily focused on incidences of EAH in organized endurance events that are conducted in the front country where medical tents and local emergency medical services are available on site to assist these participants and to transport as needed to a local hospital for appropriate management. Beyond front country triathlons and marathons, many prolonged individual activities, ultramarathons, and multiday endurance events take place in the backcountry.

To date in the backcountry, EAH has been documented in hikers, trekkers, climbers, and cold climate endurance athletes.9–14 Furthermore, it is likely that many individuals with symptomatic or asymptomatic EAH go underreported in the literature.15 The lessons learned from current evidence-based EAH guidelines can be extended to those providing care in the backcountry in a limited-resource environment. Thus, it was the intent of this panel to develop evidence-based practice guidelines for EAH for use in austere environments, during transport by emergency medical services, and for immediate care by the receiving hospital.

**Methods**

The expert panel was convened at the Wilderness Medical Society annual meeting in Whistler, British Colum-
bia, Canada, July 2012. Members were selected based on clinical interest or research experience. Relevant articles were identified by a search of MEDLINE as the primary database, US National Library of Medicine, National Institutes of Health (http://www.ncbi.nlm.nih.gov/pubmed/). Key search terms used were hyponatremia, exercise-associated hyponatremia, arginine vasopressin, syndrome of inappropriate antidiuretic hormone (SIADH), hyponatremic encephalopathy, and 3% hypertonic saline. Peer-reviewed studies related to EAH including randomized controlled trials, observational studies, and case series were reviewed, and the level of evidence supporting the conclusions was assessed. Abstract-only studies were not included. Conclusions from review articles were not considered in the formulation of recommendations but are cited below in an effort to provide context. When no relevant studies were identified, the expert panel recommendation was based on risk vs benefit perceptions derived from patient-care experience. The panel used a consensus approach to develop recommendations regarding management of EAH in the wilderness. These recommendations have been graded based on clinical strength as outlined by the American College of Chest Physicians (ACCP; Table 1).16

**Scope of the Problem**

EAH typically occurs during or up to 24 hours after prolonged physical activity, and is defined by a serum or plasma sodium concentration below the normal reference range of 135 mEq/L.7 The reported incidence of EAH varies widely, in part because the diagnosis is based solely on an abnormal biochemical result in an appropriate clinical setting. Many cases of EAH may be asymptomatic and are largely detected from blood samples taken from consenting athletes participating in research screening protocols with reported incidence ranges from 0% to 51%. The highest reported incidence of “asymptomatic” hyponatremia has been noted in ultramarathon races covering 161 km (100 miles) in North America, in which the incidence of EAH has ranged between 30% and 51%.13,17–19

The incidence of asymptomatic EAH is greater than the incidence of “symptomatic” EAH, which refers to a biochemical diagnosis of EAH combined with clinical symptoms and signs. Severe EAH manifests as significant mental status changes resulting from cerebral edema (termed exercise-associated hyponatremic encephalopathy [EAHE]), at times associated with noncardiogenic pulmonary edema.5,6 Twelve confirmed deaths of public record have been directly attributed to complications associated with EAHE.20–24 The overall incidence of symptomatic EAH in all marathon participants is generally less than 1%,24,25 but the percentage of EAH seen in all symptomatic athletes seeking medical care has been reported to be as high as 23% in an Ironman Triathlon26 and 38% in runners participating in a marathon and ultramarathon in Asia.27 An increasing trend is that

ACCP, American College of Chest Physicians; RCT, randomized controlled trial.
symptomatic EAH is now being reported in much shorter distance events, such as a half marathon and sprint triathlon taking approximately 90 minutes to complete.

Symptomatic cases of EAH have been reported with increased frequency in both hikers and military infantry personnel. The reported incidence of hyponatremia in Grand Canyon hikers seeking medical care from exercise-associated collapse or exhaustion from May 31, 1993, through September 31, 1993, was 16% with an estimated incidence rate between 2.0 and 4.0 per 100,000 persons.

US military services have reported an increased trend of EAH cases primarily in marine corps and army infantry personnel with 4 reported deaths from EAH. Between 1999 and 2011, there were 1329 incident diagnoses of EAH (incidence of 12.6 per 100,000 person-years) among active-duty members. This incidence represents an increase from the previous military surveillance taken between 1997 and 2005, which documented an incidence of 1.0 to 3.0 per 100,000 person-years across all military. The US Marine Corps had the highest incident rate in 2011 at 20.9 per 100,000 person-years despite the fact that EAH preventive measures aimed at reducing excessive forced fluid intake were adopted in 1998 by services for all infantry and other personnel. Thus, these data on military personnel reveal that their reported modest hiking and marching activities in young and healthy individuals have led to documented EAHE morbidity and mortality.

**Pathogenesis of EAH**

Two major pathologic mechanisms largely account for the development of EAH: 1) excessive fluid intake, and 2) impaired urinary water excretion, largely as a result of persistent secretion of arginine vasopressin (AVP), also referred to as antidiuretic hormone or ADH.

**EXCESSIVE FLUID INTAKE**

Overhydration appears to be the primary risk factor for the development of EAH. This is reflected in the weight gains seen in the majority of, but not all, athletes who become hyponatremic. Individuals with normal renal function, ingesting a regular diet, can excrete between 500 and 1000 mL/h of water. With the additional, non-renal losses of water due to sweat and insensible fluid losses, athletes should be able to consume as much as 1000 to 1500 mL/h before developing water retention and dilutional hyponatremia. Thus, although fluid ingestion is necessary to develop EAH, it is likely not sufficient except in those circumstances in which water intake is very excessive (>1500 mL/h).

**INAPPROPRIATE AVP SECRETION**

Failure to suppress AVP can markedly reduce the ability of the kidneys to excrete a water load. For instance, in normal circumstances, ingestion of excessive water should suppress AVP, leading to production of dilute, high-volume urine (urine osmolality as low as 50 mOsm/kg and a volume of 500 to 1000 mL/h). If AVP is not suppressed appropriately with water loading, then the ability to produce dilute urine is markedly impaired (for instance, a low-level persistence of AVP can result in a fixed urine osmolality of 150 mOsm/kg and a decrease in the rate of water excretion by two thirds as compared with a urine osmolality of 50 mOsm/kg). In fact, the available data support the concept that many athletes who experience EAH have submaximal suppression of AVP and an inappropriately high urine osmolality. This is similar to SIADH. There are a number of non-osmotic stimuli that lead to secretion of AVP that may be operable in endurance athletes: intense exercise itself, nausea or vomiting, hypoglycemia, and nonspecific stresses such as pain and emotion. Not all AVP release in athletes may be inappropriate as excessive sweat losses may induce volume depletion and appropriate secretion of AVP. This appropriate AVP secretion may be important in those athletes who experience EA along with net weight loss (Figure 1).

**OTHER FACTORS**

Although the combination of excessive water intake and inappropriate AVP secretion will clearly lead to hyponatremia, other factors may be operable in endurance athletes. In a study of endurance athletes running for a mean of 6 hours with ad libitum fluid intake, it was noted that even with a mean 3.8-kg mass loss, serum sodium was...
maintained at normal levels. Despite the loss in plasma volume in these subjects, there were elevations in the levels of brain natriuretic peptide (NT-BNP). The elevations in NT-BNP may lead to excessive losses of urine sodium and raise the risk of hyponatremia.

A possible mechanism for maintenance of a normal serum sodium level despite weight gain is the release of sodium from internal stores. Up to 25% of body sodium is bound in bone (to negatively charged proteoglycan matrix) and, although not osmotically active, is potentially recruitable into an osmotically active form. Thus, this pool could minimize the fall in serum sodium induced by overhydration or exacerbate hyponatremia if not mobilized.

The absorption of water retained in the gastrointestinal tract at the end of a race has been suggested as a cause for an acute drop in serum sodium concentration. This may account for a transient lucid period after finishing a race followed by the acute development of clinical signs of EAHE within about 30 minutes after a competition. The breakdown of glycogen into smaller, more osmotically active molecules, such as lactate, during exercise initially increases cellular osmolality and shifts water into cells, leading to a rise in serum sodium. This may then reverse within 5 minutes after the cessation of exercise and transiently lower the serum sodium. Changes in potassium balances that serve as effective osmoles may also affect the serum sodium such that hypokalemia will lead to or exacerbate hyponatremia.

The issue of whether sweat sodium loss contributes to the development of EAH remains controversial. There is a highly variable degree of sodium loss from sweat (ranging from 15 to 65 mEq/L), and as compared with the general population, endurance athletes generally have lower sweat sodium levels. The direct effect of losing hypotonic sweat would be to raise the serum sodium. However, sweat loss could contribute to the development of hyponatremia if the degree of fluid loss were sufficient to produce significant volume depletion and provide a stimulus to AVP release and, thereby, impair urine excretion of water. In this case, there would also explain the finding of EAH developing in some athletes with net weight loss.

**Risk Factors**

As stated above, the major risk factor for developing EAH is excessive water intake beyond the capacity for renal water excretion. Other independent risk factors include longer race times (continuous endurance exercise lasting >4 hours) and a low or high body mass index (BMI). Practically speaking, smaller athletes (low BMI) who are following fluid intake guidelines designed for larger individuals and slower, unfit athletes (high BMI) drinking generous amounts of fluids because they are exercising at a lower intensity are at increased risk for experiencing hyponatremia during exercise. Although the incidence of women experiencing symptomatic hyponatremia appears to be greater than that of men in some environments, when adjusted for BMI and racing time, the apparent sex difference has not been shown to be statistically significant.

Along with other nonosmotic stimuli to AVP secretion, nonsteroidal anti-inflammatory drugs (NSAIDs) have been implicated as a risk factor in the development of EAH by potentiating the water retention effects of AVP at the kidney. However, data are still conflicting and further investigation is necessary to determine whether NSAID usage—with respect to both classification and dosages—is a clear risk factor for the development of EAH. Other medications associated with SIADH such as selective serotonin reuptake inhibitors may also increase the risk for EAH, but data are not conclusive.

**Prevention**

**AVOID OVERHYDRATION**

The primary strategy to prevent EAH is to avoid overdrinking during exercise. Because fluid losses through sweat and urine are highly dynamic and variable across individuals participating in a variety of outdoor activities, recommending “fixed ranges” of fluid intake are not appropriate. Using the sensation of thirst as a real-time guide to fluid ingestion during exercise appears safe and effective and eliminates both of the detrimental extremes of fluid balance (dehydration and overhydration). Therefore, participant education on this approach to hydration during exercise is an important prevention strategy. Another strategy that has been shown to reduce the incidence of hyponatremia during endurance events is to reduce the availability of fluids along the routes of exercise.

**Recommendation:** Participants should focus on decreasing overdrinking during exercise by drinking according to thirst, and race organizers might consider reducing the overavailability of fluids (<3 km apart) along routes of exercise. Recommendation Grade: 1C.

**AVOID EXCESSIVE SODIUM SUPPLEMENTATION**

Sodium supplementation during exercise has not been shown to prevent the development of hyponatremia dur-
ing physical activity lasting less than 18 hours.64–67 In athletes who drink beyond thirst or fully replace 100% of body weight losses during exercise, supplemental sodium may attenuate the decline in blood sodium concentration67,68 but will not prevent the development of hyponatremia if overdrinking were to continue.65 Supplemental sodium has no effect on blood sodium concentration when athletes drink according to thirst.64–66 However, exercisers who drink insufficient amounts of fluid during exercise will often finish races with elevated blood sodium concentrations.69–72 Collectively, these results demonstrate that it is the amount of fluid ingested rather than the amount of sodium ingested during exercise that has a more pronounced effect on blood sodium concentrations as mathematically predicted elsewhere.73 Adverse effects associated with abnormal water retention from excessive sodium intake have been reported.74

**Recommendation:** Excessive sodium supplementation is not recommended during physical activity lasting less than 18 hours. Recommendation Grade: 2B.

**MONITORING BODY WEIGHT**

Because overconsumption of hypotonic fluids beyond the capacity to excrete any fluid excess is often key in the pathophysiology of EAH, the monitoring of body weight change is one strategy commonly used in 161-km ultramarathons to help prevent overhydration. As a result of the combination of substrate losses and the liberation of glycogen-bound water during exercise, some weight loss is appropriate during exercise. Furthermore, EAH has been reported with substantial weight loss in some environments.17–19 So weight loss is not a reliable approach for excluding the diagnosis of EAH. On the other hand, in the presence of weight gain during exercise, fluid intake should be reduced, and if sodium supplementation has been taking place, this should also be curtailed until body weight returns to an appropriate level. If feasible, weight scales can be made available at organized athletic events for this purpose, but care should be taken to assure proper scale calibration and placement on solid level surfaces, and participants should be educated in proper use of body weight information.

**Recommendation:** Body weight can be monitored in organized events, and in the presence of weight gain during exercise, fluid and sodium intake should be reduced until weight returns to 2% to 4% of body weight loss from baseline level. Recommendation Grade: 1B.

**EDUCATE EVENT SUPPORT AND MEDICAL PERSONNEL**

Event support staff should have a basic understanding of EAH to avoid the provision of improper hydration advice to participants because it has been previously shown that runners have a poor understanding of the relationship between drinking habits and hyponatremia.75,76 On-site medical personnel should be aware of proper treatment of EAH. This should include the recognition that hypotonic fluid replacement (intravenous or oral) should be avoided when the diagnosis of EAH is under consideration to prevent further declines in blood sodium concentration. Such education can be provided by event medical directors via prerace briefings and the use of suggested reading material or educational videotapes.

**Recommendation:** Event support staff should be educated so they can provide proper hydration advice, and on-site medical and emergency medical service (EMS) personnel should be educated about proper recognition and treatment of EAH. Recommendation Grade: 1C.

**Field Treatment**

Appropriate management of EAH depends first on correctly diagnosing the condition. A requisite for correctly diagnosing EAH is that it must be routinely considered in the differential diagnosis of an individual presenting for medical attention during or shortly after exercise or strenuous activity. In fact, EAH can easily be mistaken for dehydration, heat illness, or acute altitude illnesses.22,23,25,78,79 because of overlapping signs and symptoms if the diagnosis is not considered (Table 2). Differentiation between dehydration and EAH is critical as provision of isotonic or hypotonic fluids is appropriate for the dehydrated athlete,80 whereas such treatment could be disastrous for an athlete with EAH, in whom the administration of these hypotonic or isotonic fluids may worsen hyponatremia.22,23,25,78

A conclusion of the Second International Exercise-Associated Hyponatremia Consensus Development Conference was that “medical directors should ensure the availability of onsite serum sodium concentration analysis.”7 When EAH is routinely considered in the differential diagnosis of a collapsed athlete and point-of-care serum sodium concentration analysis is available, the field diagnosis of EAH becomes straightforward. However, the reality is that on-site analysis of serum sodium concentration is not widely available at organized endurance competitions nor is it currently feasible to implement. Even relatively large and established events often have no capacity for on-site blood analysis. This is also the case with most wilderness activities.
Therefore, we provide strategies for the following 2 scenarios (Figure 2).

Scenario 1: An EAH diagnosis has been made by point-of-care sodium analysis.
Scenario 2: Point-of-care sodium analysis is not available, and the diagnosis of EAH is presumed.

**THERAPEUTIC OPTIONS FOR BOTH SCENARIOS**

**Fluids**

An important element in the treatment of EAH is to avoid exacerbating the condition with improper fluid management. If EAH is clinically suspected, an assessment of volume status should be considered before treatment with IV fluids is rendered. It must be made clear that inappropriate IV fluid administration risks worsening hyponatremia with potentially devastating consequences. Thus, clear indications (such as unstable blood pressure) should be present to support administration of IV fluids. The use of hypotonic IV fluids should be avoided. If the patient does not have clear indications for IV fluids and EAH is suspected, then fluid restriction while the patient is being transported to a medical center should be instituted.

**Recommendation:** Hypotonic or isotonic fluid intake should be restricted in known or suspected EAH until urination begins. Recommendation Grade: 1A.

**Supplemental oxygen**

Hypoxemia from pulmonary edema has been reported in EAH. As a supportive intervention, supplemental oxygen (flow rate 2–4 L/min nasal) should be provided to treat any respiratory distress if available.

**Recommendation:** Respiratory symptoms should be supported with supplemental oxygen if available. Recommendation Grade: 1C.

**Appropriate transfer of care**

The intent of field management is to stabilize the patient until their care can be transferred to a definitive care medical facility. Unfortunately, EAH recognition is challenging, and appropriate management is not universally understood. Therefore, when transferring care, it is critical to relay the potential diagnosis of EAH and to caution the transport team about the dangers of aggressive IV hydration with isotonic or hypotonic fluids. Ideally, an IV saline lock should be placed for EMS transport, and the provision of IV fluids should be based on

</table>
clear indications of marked hypovolemia such as sustained hypotension. However, if the transport team insists on provision of isotonic or hypotonic fluids, they should be cautioned that a patient with EAH could experience worsening symptoms with this intervention. If symptoms worsen in this scenario, IV fluids should be stopped, and consideration of immediate hypertonic (3%) saline administration should occur.

**Recommendation:** When transferring care, alert receiving caregivers of the diagnosis of EAH and appropriate management. **Recommendation Grade:** 1C.

### SPECIFIC RECOMMENDATIONS—SCENARIO 1
(BLOOD SODIUM ESTIMATION IS AVAILABLE)

#### Clinical assessment

The portability of point-of-care testing devices means that they may be available to confirm a diagnosis of EAH (for instance at a mass-participation wilderness sporting event or on a well-equipped expedition). In general, a sodium level of 130 mmol/L or higher will be minimally symptomatic or asymptomatic, whereas levels below this are increasingly likely to be symptomatic. Symptoms and signs of EAHE (ranging from headache and nausea or vomiting to confusion and obtundation) are a key element in making the diagnosis of severe or clinically significant findings. Although the early symptoms of EAH may be nonspecific, the presence of altered mental state, coma, seizures, or respiratory distress (suggesting pulmonary edema) indicates EAHE and should be promptly recognized.

**Recommendation:** A rapid assessment for signs and symptoms of cerebral edema or noncardiogenic pulmonary edema should be made in all patients with possible EAH. **Recommendation Grade:** 1B.

Developing signs of cerebral or pulmonary edema (noncardiogenic) signify an urgent medical condition requiring emergent care. In such situations, urgent blood sodium measurement is invaluable in guiding initial therapy.

**Recommendation:** When point-of-care sodium analysis is available in the field and EAH is suspected, blood sodium measurement should be obtained as rapidly as possible. **Recommendation Grade:** 1B.

#### Hypertonic saline

It is possible to commence and indeed even complete treatment for EAH in the field. Individuals with EAH who are neurologically stable can be advised to limit fluid intake and consume salty snacks, soups or bouillon, or a small volume of hypertonic fluid until the

---

**Figure 2.** Algorithm for exercise-associated hyponatremia (EAH) field management.
onset of urination. They should be observed for at least 60 minutes during the initial postexercise period because water remaining in the gastrointestinal tract can be quickly absorbed at the cessation of exercise and result in rapid development of symptoms from EAH. More urgent medical attention, including planning for transfer to definitive care, is required if signs or symptoms of EAH develop. Once any neurological symptoms more serious than headache develop, regardless of the degree of hyponatremia, treatment with hypertonic saline is indicated. When able to tolerate oral intake, a hypertonic (\( \sim 9\% \) saline) solution of concentrated broth (3–4 bouillon cubes in 125 mL [\( \frac{1}{2} \text{ cup} \) of water]) would be an appropriate initial treatment.83

**Recommendation:** Oral hypertonic saline solutions are an appropriate intervention in the field for cases of EAH when oral intake is possible. Recommendation Grade: 1C.

If the individual is unable to tolerate oral intake, or when there is no improvement or symptoms worsen with oral hypertonic saline, the recommended treatment is a 100-mL bolus of 3% hypertonic saline infused through a peripheral vein in less than 60 seconds. This can be repeated 2 additional times at 10-minute intervals if there is no clinical improvement.7,25,82,83 Experience has proven this treatment to be without untoward symptoms at the infusion site (no burning, phlebitis, or residual discomfort) and no risk of osmotic demyelination or central pontine myelinolysis.7

**Recommendation:** Symptomatic biochemically confirmed EAH can be treated in the field with a 100-mL bolus of 3% hypertonic saline, which can be repeated twice at 10-minute intervals (3 doses in total) with the aim of acutely increasing serum sodium concentration by about 4 to 5 mmol/L and reversing cerebral edema in the setting of acute hyponatremia. Recommendation Grade: 1B.

**SPECIFIC RECOMMENDATIONS—SCENARIO 2**

**(BLOOD SODIUM ESTIMATION IS NOT AVAILABLE)**

When the capacity for onsite serum sodium measurement is not available, the decision-making process becomes challenging. Unfortunately, the possible signs and symptoms that can be present with EAH are quite similar to those present with heat illness, dehydration, or acute mountain sickness (Table 2). Furthermore, there were no differences between those experiencing mild EAH and those not experiencing EAH after a 161-km ultramarathon in terms of various individual characteristics, signs, and symptoms.81 Even oliguria, which would be typical of the dehydrated state, is also commonly seen with EAH when AVP secretion is part of the pathophysiological mechanism leading to a highly concentrated, low-volume urine output.23

In some environments in which overhydration is a key feature in the underlying etiology of EAH, those experiencing EAH have been shown to be more likely to lose less weight or to gain weight during the exercise compared with those not experiencing EAH.41 However, in other environments, it is not at all uncommon for those with EAH to have considerable weight loss, suggesting other mechanisms in the development of EAH.17–19 Therefore, changes in body weight are not universally helpful in making the diagnosis of EAH. This unfortunately means that the only reliable method of diagnosing EAH at present is through measurement of serum sodium concentration.

**Fluid restriction**

A high clinical suspicion of EAH necessitates fluid restriction and salt supplementation. Certainly in environments such as long ultramarathon races in which the incidence of EAH may be high (30%–51%),13,17–19,82 one should resist treating athletes with IV hypotonic or isotonic saline without certainty that they do not have EAH.22,23,25,78 However, fluid restriction is contraindicated in the case of dehydration and rhabdomyolysis with impending acute kidney injury.80 Therefore, in the situation in which the diagnosis of EAH is uncertain, the potential benefits of fluid restriction if the individual has EAH must be weighed against the potential harm that could result when the individual might have dehydration, rhabdomyolysis, and impending acute renal failure.

**Recommendation:** Hypotonic or isotonic fluids should be restricted in suspected EAH with consideration toward the potential harm that could result from fluid restriction if the diagnosis is incorrect. Recommendation Grade: 2C.

**Hypertonic saline**

In the event of neurological deterioration without access to rapid determination of serum sodium concentration, the use of IV hypertonic saline, if available, is a consideration for presumed EAH. Such an intervention carries potential risks, yet the benefit that could be derived from a bolus of hypertonic saline of approximately 51 mmol of sodium for fluid volume expansion and the limited effect it would have on increasing blood sodium concentration suggest that the risk is low, even under conditions of dehydration and hyponatremia. When the patient is neurologically stable, oral sodium with limited fluid has been demonstrated to be an appropriate treatment.83
the field, this could be prepared by dissolving 3 to 4 bouillon cubes in 125 mL (½ cup) of water (~9% saline).

**Recommendation:** IV hypertonic saline (100 mL bolus of 3% hypertonic saline, which can be repeated twice at 10-minute intervals) is an appropriate consideration in suspected EAH with neurological deterioration, whereas an oral hypertonic saline solution would be an appropriate consideration in suspected mild EAH. Recommendation Grade: 2C.

**Emergency transport**

When point-of-care serum sodium concentration cannot be determined and any attempted field treatment has been insufficiently successful, emergency transport to a definitive care facility should be expedited. Organized endurance exercise events that do not have the on-site capacity for measurement of serum sodium concentration and treatment with hypertonic saline should prearrange an appropriate emergency transport system. Local emergency department physicians and transport personnel should also be educated about EAH in advance of the event.

**Recommendation:** The assurance that an emergency transport system is in place is critical when point-of-care serum sodium measurement will not be available or treatment with hypertonic saline will not be feasible. Recommendation Grade: 1C.

**IMMEDIATE MEDICAL CARE IN HOSPITAL—ASSESSMENT**

The medical care of suspected EAH in hospital is assumed to occur in a facility that has the capacity to measure an urgent sodium level either by point-of-care testing or in a hospital laboratory. The sodium level and a clinical assessment for signs of cerebral edema are the key factors that will determine urgent treatment. The primary intervention (when indicated) is the use of IV hypertonic saline (HTS), usually as a 3% solution, to acutely increase serum sodium and reduce cerebral edema, whereas the role of other therapeutic agents such as vasopressin receptor antagonists (“vaptans”), urea, oral saline solutions, and diuretics in the treatment of acute symptomatic cases of EAH has not been firmly established. See Table 3 for a summary of critical steps for immediate medical care in a receiving hospital.

**Urgent sodium estimation**

The in-hospital diagnosis of EAH is made in an appropriate clinical context, whether or not signs or symptoms are present, by the determination of a sodium level below the normal reference range. In general a sodium level of 130 mmol/L or higher will be minimally symptomatic or asymptomatic, whereas levels below this are increasingly likely to be symptomatic. Developing signs of cerebral edema signify an urgent medical condition requiring emergent care.

**Recommendation:** With suspected EAH, and especially those with altered mental state, sodium estimation should be obtained as rapidly as possible after hospital arrival. Recommendation Grade: 1B.

**Assessment for cerebral and pulmonary edema**

Symptoms and signs of cerebral edema are a key element in making the diagnosis of severe or clinically significant EAH. Although the early symptoms of EAH may be nonspecific, the presence of altered mental state, coma, seizures, or respiratory distress (suggesting pulmonary edema) indicates severe EAH. Such an assessment is made clinically at the bedside. It does not require imaging or scans and should never delay the use of IV HTS when indicated (see following sections).

**Recommendation:** A rapid assessment for signs and symptoms of cerebral edema and/or non-cardiogenic pulmonary edema should be made in all patients with possible EAH. Recommendation Grade: 1B.
**Other laboratory testing**

Although not essential to guide initial therapy, there are other laboratory tests that can help to better delineate the pathophysiology of EAH in an individual patient and help guide subsequent treatment if more prolonged in-hospital care is required. These tests may help to differentiate euvolemic from hypovolemic EAH and the role of AVP in its pathogenesis. Such tests are best taken before therapy is commenced even if they are only stored for subsequent analysis. However, such testing should never delay the use of IV HTS when indicated (see following sections).

**Recommendation:** When possible, urine for sodium and osmolality and blood for osmolality should be obtained before commencement of treatment. 

**Recommendation Grade:** 2C.

**Fluid restriction**

Mild or asymptomatic EAH (essentially a biochemical-only diagnosis) will usually resolve without treatment during a period of observation. Hypotonic fluids, whether taken orally or given IV, will generally worsen the situation, especially before the onset of urination. IV normal saline will worsen EAH acutely in the presence of osmotically inappropriate (nonosmotic) AVP secretion (SIADH), but may be required later in specific clinical contexts such as the prevention of renal injury in rhabdomyolysis or the treatment of hypovolemic shock.

**Recommendation:** Oral and IV hypotonic or isotonic hydration should be avoided early in the management of EAH although it may be appropriate in certain clinical contexts once sodium correction has been initiated or hypovolemia is biochemically confirmed (by elevated blood urea nitrogen and urine sodium less than 30 mmol/L). 

**Recommendation Grade:** 1B.

**Hypertonic saline**

The most commonly available form of IV HTS is a 3% solution. Hypertonic saline will acutely raise the serum sodium, resulting in a fluid shift that will decrease cerebral edema. A 100-mL solution of 3% HTS contains 51 mmol of sodium and in the average adult would be expected to increase the serum sodium by 1 to 2 mmol/L. It is used whenever there are signs of significant cerebral edema in EAH. It may also be indicated in severe biochemical hyponatremia (≤125 mmol/L) when initially presenting as asymptomatic or mildly symptomatic, as these cases have been known to progress to EAHE. When using IV HTS, the aim is not to normalize the serum sodium concentration but rather to reverse cerebral edema while preventing or treating the life-threatening consequences of EAHE. Generally this will require an increase in the sodium level of about 4 to 5 mmol/L. Thereafter, further normalization of sodium is not urgent and may be best allowed to occur spontaneously through suppression of nonosmotic AVP secretion and resultant urinary free water excretion. The use of IV HTS in EAH appears to be safe, with no recorded cases of osmotic demyelination known to have occurred as opposed to the situation with rapid correction of chronic hyponatremia.

**Recommendation:** In hospital, severe biochemically confirmed or symptomatic EAH should be treated with a 100-mL bolus of 3% hypertonic saline, which can be repeated twice at 10-minute intervals (3 doses in total), with the aim of acutely increasing serum sodium concentration by about 4 to 5 mmol/L and reversing cerebral edema. 

**Recommendation Grade:** 1A.

**Supplemental oxygen**

Although the major manifestation of EAH is cerebral, pulmonary manifestations can occur. Hypoxemia, which may worsen cerebral injury, should be avoided, but hyperoxia may possibly have detrimental effects.

**Recommendation:** Supplemental oxygen to maintain an oxygenation saturation of 95% should be provided to treat hypoxemia from pulmonary edema when evident. 

**Recommendation Grade:** 1C.

**Conclusions**

Exercise-associated hyponatremia has a complex pathogenesis and multifactorial etiology. It can result in devastating outcomes to participants in both organized or individual endurance activities in communities or in remote backcountry environments.

Preventing EAH is the key factor in protecting participants in endurance events and other wilderness activities. Currently, there is no one recommendation that fits all individuals for fluid and salt consumption during endurance events, although prudent general guidelines include drinking to thirst and specifically avoiding excessively high fluid intake. There is an ongoing need for education to ensure that participants understand the risk of overhydration. Furthermore, a knowledge gap persists internationally among practitioners and prehospital EMS personnel about the assessment and treatment of EAH, which is compounded by the nonspecific nature of many of the signs and symptoms of EAH. The typical field response is to administer rapid isotonic IV fluids to endurance activity participants in the suspicion they are...
dehydrated. However, such universal treatment may result in increased morbidity and mortality in the asymptomatic and symptomatic EAH patient.
